COLOR STABILITY OF ARTIFICIAL WHITE SPOT LESIONS TREATED WITH RESIN INFILTRATION

Marwa I. AbdelHafez *, Dena S. Mustafa ** and Khaled A. Nour ***

ABSTRACT

Objective: To evaluate the color stability of artificial white spot lesions treated with three different surface treatments after immersion in staining solution.

Materials and Methods: An artificial white spot lesion was created in the middle of the labial surface using demineralizing solution. Sixty-five bovine teeth were randomly assigned into 5 groups (n=13) according to surface treatment. G1: Enamel submitted to demineralization only. G2: Polished Enamel. G3: Demineralized enamel treated with low-viscosity resin infiltrant. G4: Demineralized enamel treated with CPP-ACP for 1 month. G5: Demineralized enamel treated with Artificial saliva for 1 month. All specimens were then immersed in a staining solution (coffee) for 8 weeks. Color measurements, using the CIE L*a*b* system, were done immediately after treatment and after 2, 4 and 8 weeks of immersion, by Spectrophotometry. Digital photographs were also taken at each stage to a representative specimen from each group. In addition, representative specimen for each group was evaluated using Polarized Light microscope. Color change (ΔE) was analyzed by two-way mixed ANOVA.

Results: Resin infiltrant group exhibited the lowest color change values at all times of measurement, followed by CPP-ACP and polished enamel, while the highest color change values were recorded in samples without treatment.

Conclusion: Resin infiltrant can be considered an effective treatment in masking and reducing long-term staining susceptibility of white spot lesions after treatment.

KEYWORDS: Color stability, Artificial white spot lesion, Resin infiltrant, Amorphous calcium phosphate, Spectrophotometer.
INTRODUCTION

White spot lesions are considered the earliest evidence of dental caries, which can be caused by imbalance between demineralization and remineralization processes. White spot lesions can present on any tooth surface where the microbial biofilm is allowed to develop and remain for a prolonged period of time.

The subsurface porosity of WSLs caused by enamel demineralization develops a different refractive index (1.00) than hydroxyapatite (1.62-1.65), and is noticeable when dehydration of the lesion is performed. This heterogeneity leads to light scattering and the appearance of dull whitish discoloration. Increased opacity is correlated to extensive and increased porosity. When these porosities are filled with an aqueous solution having similar refractive index to hydroxyapatite, the opacity seemingly disappears and enamel regains its translucency.

Several treatments have been proposed for arresting the lesion and masking this whitish discoloration, starting from management of the dietary habits and utilizing a therapeutic spectrum that saves the pseudo-intact surface layer maintaining tooth integrity and blocking the porosities against further diffusion of acids and chromophores.

Non-invasive treatments aim at arresting or reversing the white spot lesions. It involves topical application of remineralizing agents on the enamel surface. They may be in the form of pastes, cream like casein-phosphopeptide - Amorphous calcium phosphate (CCP-ACP), or varnishes like fluoride. These treatments can effectively promote remineralization of the sub-surface lesions. However, these agents are subject to dilution and washing out by saliva. They also require time and patient compliance.

Further along the therapeutic spectrum, micro-invasive techniques involve filling the pores within the body of the lesion with a low-viscosity light-cured resin, therefore, preventing further dissolution of enamel by acidic challenges. The concept of resin infiltration has been proposed in order to combine both non-invasive and immediate esthetic outcomes in more challenging WSLs. Owing to its low viscosity, resin infiltrant (ICON®) can fill the pores and thus prevents further diffusion of bacteria, and consequently, impedes lesion development.

In addition, resin infiltration has the ability to mask the whitish, opaque color of the lesion by altering its refractive index to approach that of the remaining tooth structure and therefore enhancing the final tooth appearance.

Since white spot lesions are often present in the esthetic zone, huge efforts have been made to mask their opaque color. In addition, color stability of different treatment modalities are very important in evaluating their long-term success. Even more, further testing of these materials for their staining susceptibility when exposed to different colorants is still needed.

From this aspect, this study aims to evaluate the color stability of artificial white spot lesions treated with resin infiltrant, or remineralization, by either CPP-ACP or artificial saliva after immersion in a staining solution.

MATERIALS AND METHODS

Specimen preparation

Bovine teeth were cleaned from blood and soft tissue. Each specimen was placed in a cylindrical PVC ring, with the labial surface directed downwards on a glass slab to embed in self-polymerizing acrylic resin (Acrostone, Egypt). For standardized and repeated positioning of specimens at the different times of measurements, a groove was made on the side of each resin block using fissure bur (MANI®, Japan). Enamel surfaces were then polished with silicon carbide polishing papers (180, 600, 1200 grits) in ascending fineness followed by ultrasonic
cleaning for 15 minutes to ensure removal of all surface debris.\textsuperscript{15,16}

**Grouping of specimens**

Sixty-five bovine teeth were randomly assigned into five groups (n=13) according to surface treatment. G1: Enamel submitted to demineralization only; without treatment. G2: Polished Enamel. G3: Demineralized enamel treated with resin infiltrant. (ICON®, DMG, Hamburg, Germany). G4: Demineralized enamel treated with CPP-ACP for 1 month. (GC Tooth Mousse®, GC Tokyo, Japan). G5: Demineralized enamel treated with Artificial saliva for 1 month. Sample size calculation was performed using G*Power (Version 3.1.9.2 2) to set power = 95\%.\textsuperscript{1}

**Preparation of artificial white spot lesions:**

The working area of each specimen was demarcated using a 6mm×6mm graph paper in the middle of the labial surface representing the area exposed to demineralizing solution. The rest of the enamel surface was protected by two coats of acid-resistant nail varnish (Revlon Consumer Products Corporation, New York, USA).\textsuperscript{17,18} Specimens were immersed in a demineralizing solution containing 2.2 mM CaCl\(_2\), 2.2 mM KH\(_2\)PO\(_4\), and 50 mM Acetic Acid at 37°C for 4 days.\textsuperscript{19} Two milliliters of demineralizing solution was used per each mm\(^2\) of the exposed enamel area of each specimen.\textsuperscript{14}

**Surface treatment of artificial white spot lesions:**

Specimens were exposed to three different surface treatments (resin infiltrant, CPP-ACP and artificial saliva). For the **Resin infiltration** group, resin infiltrant (ICON\(^8\)) was applied according to the manufacturer’s instructions.\textsuperscript{20} Hydrochloric acid etchant was applied followed by Icon-Dry and Icon-Infiltrant. Any excess beyond the lesion peripheries was removed before curing. A layer of glycerin was then applied and light-cured.\textsuperscript{21} The infiltrated surfaces were polished according to manufacturer instructions to remove any surface irregularities.

For the **CPP-ACP** group, WSLs were treated with GC Tooth Mousse\(^6\) for 30 minutes and the excess was removed with gauze. Specimens were then rinsed and stored in artificial saliva until the next day.\textsuperscript{53} This remineralization procedure was repeated for 30 days at the same hour and the artificial saliva was changed every day.\textsuperscript{23}

For the **Artificial saliva** group, specimens were stored in artificial saliva of pH 7.0 containing 0.65g/l potassium chloride, 0.058 g/l magnesium chloride, 0.165g/l calcium chloride, 0.804g/l dipotassium hydrogen phosphate, 0.365g/l potassium dihydrogen phosphate, 2g/l sodium carboxymethyl cellulose and distilled water. The solution was renewed daily for 30 days.\textsuperscript{24}

**Staining procedure**

Coffee was selected as the staining solution in this study. A sachet of 1.8g of coffee powder (Nescafe\(^8\) Classic, Nestlè, Switzerland) was poured into 200 mL of hot water and stirred. The solution was left to cool at room temperature. Each specimen was immersed individually in a separate jar containing coffee and stored at room temperature. Over the span of 8 weeks of immersion, staining solution was changed every 7 days to prevent the growth of bacteria and fungi.\textsuperscript{14,25}

Prior to color measurement, specimens were re-polished, rinsed and blot-dried using absorbent papers, then color measurements were obtained.\textsuperscript{51}

**Colorimetric analysis:**

Digital photographs of representative specimens were obtained under standardized photography settings using DSLR camera. Images were taken immediately after treatment of WSLs and after 2, 4 and 8 weeks of immersion in coffee.

In addition, color measurements were obtained for all the groups according to the Commission International de l’Eclairage (CIE) L* a* b* values, using Cary 5000 Spectrophotometer (Agilent Technologies, NY, USA). Color measurements
were obtained immediately after treatment and after 2, 4 and 8 weeks of immersion.

Results of color measurements were quantified in terms of three coordinate values \( (L^*a^*b^*) \), \( L^* \) represents the degree of Lightness (0 black, 100 white), \( a^* \) represents the degree of green/red color, \( b^* \) represents the degree of blue/yellow color. The quantitative evaluation of color change (\( \Delta E \)) of the test specimens were obtained by the following formula:\(^{14}\)

\[
\Delta E = (\Delta L^2 + \Delta a^2 + \Delta b^2)^{1/2}
\]

A \( \Delta E \) difference of \( > 3.7 \) units is considered a clinical indicator for color change. Hence, \( \Delta E \leq 3.7 \) is considered acceptable for color change.\(^{43,46,57}\)

**Polarized Light Microscopy**

A representative sample for each group was prepared to be studied under Polarized Light microscopy before the process of staining. Samples were sectioned longitudinally and mounted on a glass cover slide.\(^8\) The intended area of WSL was centered in the field of view and photographed at \( \times 10 \) magnification using Polarized light microscopy (BX60, Olympus, Japan).

**Statistical analysis**

Two-way mixed model ANOVA was used to study the effect of different tested variables and their interaction on color stability of artificial WSLs. The significance level was set at \( p \leq 0.05 \) within all tests.

Mean and standard deviation for each group was calculated. Statistical analysis was performed with IBM® SPSS® Statistics Version 26 for Windows (IBM Corporation, NY, USA).

**RESULTS**

Two-way mixed ANOVA test results revealed a significant effect of surface treatment, time of immersion, and their interaction on color change of artificial WSLs \( (p < 0.001) \) as shown in Table 1.

One-way ANOVA revealed a statistically significant effect of surface treatment on color change of artificial WSLs \( (p < 0.001) \). The highest value of color change was found in samples without treatment, followed by artificial saliva. Meanwhile, the lowest color change value was recorded by resin infiltration group as shown in Table 2. Pairwise comparisons using Tukey’s post hoc test revealed no significant difference between samples treated with CPP-ACP and polished enamel \( (p =0.253) \).

One-way repeated measures ANOVA recorded a significant effect of time of immersion on color change of artificial WSLs \( (p < 0.001) \) as shown in Table 2. Pairwise comparisons utilizing multiple paired \( t \)-tests with Bonferroni correction showed a statistical significant increase of color change values starting at 2 weeks, followed by 4 weeks; reaching the highest color change value at 8 weeks after immersion in staining solution \( (p < 0.001) \).

As shown in Table 3, after 8 weeks of immersion in coffee solution, the highest ΔL value was recorded by the resin infiltration group, while the lowest ΔL value was found in samples without treatment. Meanwhile, Δa value was the highest in samples without treatment, while the lowest Δa value was found in CPP-ACP group. Nevertheless, Δb values were the highest in the artificial saliva group, while the lowest Δb value was found in polished enamel samples.

POLARIZED LIGHT MICROSCOPIC EVALUATION OF ENAMEL SURFACE:

Fig. (1): Polarized light micrograph of longitudinal ground section (x10) showing (a) artificially demineralized enamel lesion with well-developed dark body of lesion. (b) homogenous enamel surface. (c) artificially demineralized enamel lesion treated with resin infiltrant. (d) artificially demineralized enamel lesion treated with CPP-ACP. (e) artificially demineralized enamel lesion treated with artificial saliva.
DISCUSSION

White spot lesions (WSLs) are early signs of demineralization process resulting in chalky white appearance of the enamel surface. Several ways have been proposed for treatment of WSLs. However, some socially consumed beverages, such as coffee, Coca-Cola and tea may result in discoloration of the WSLs even after treatment. Therefore, the aim of the present study was to evaluate the color stability of artificial WSLs treated with resin infiltration compared to CPP-ACP and artificial saliva after immersion in staining solution.

In order to test color stability, a solution exhibiting strong potential for staining both tooth structure and resinous materials was needed. Coffee was preferred for the presence of stronger chromogens as gallic acid compared to tea and cola.

Following Ertas et al. (2006) and Ardu et al. (2016), continuous immersion in coffee for a period of 8 weeks was performed to simulate 5 years of daily coffee consumption among coffee drinkers. According to the manufacturer of coffee, the average consumption time for one cup of coffee is 15 minutes and the average consumption...
quantity is 3.2 cups per day. Therefore, a 24-hour storage time was used to reflect one month of coffee consumption.12,32

Results of the present study revealed a significant effect of surface treatment on the color stability of WSLs. Color change values for resin infiltration group were the lowest among all the groups. This is further substantiated by the increased depth of penetration of resin infiltration into the body of the lesion as shown in Figure (1,c). This may be attributed to the ability of the low-viscosity resin to completely infiltrate the WSLs by capillarity action thereby blocking the pathways for chromophores as well as acids.26,33

Color change values for the resin infiltrant group were the lowest among all the groups. Nevertheless, this group exhibited a perceptible degree of staining, besides increased darkness after 8 weeks of immersion in coffee. In agreement with Borges et al. (2014)3, the hydrophilic nature of the TEGDMA-based resin matrix may have increased water sorption, facilitating stain penetration and jeopardizing the color stability of the resin.3,15

It can be noted that inadequate polymerization increases resin susceptibility to hydrolytic degradation as a reflection of lower degree of conversion of monomer, resulting in color change.14,34 The use of glycerin to prevent oxygen inhibition of polymerization also did not completely eliminate the chances for intrinsic staining.21 Furthermore, accessory polishing of the infiltrated surfaces was done to lessen surface roughness and oxygen-inhibited layer. This prevents the resin from getting easily stained by mechanical adsorption and improves the stability of the masking effect.30,35

Meanwhile, samples treated with CPP-ACP (GC Tooth Mousse®) revealed color change values higher than resin infiltration group but still lower than artificial saliva. Unlike resin infiltration, treatment with CPP-ACP resulted in partial penetration to full lesion depth, as shown in Figure (1,d). This may be due to the short application period of only 4 weeks as CPP-ACP is a slow treatment process because of its dependence on the deposition of calcium ions.36 Consequently, enamel pores may have been inadequately filled with the remineralizing agent, resulting in incomplete masking of the WSLs.37 Therefore, higher color change values and increased darkness upon staining.31

Samples immersed in artificial saliva showed color change values higher than both CPP-ACP and resin infiltration. One possible explanation is that artificial saliva resulted only in deposition of minerals on the surface layer leaving the body of the lesion demineralized.3,31,38 This incomplete penetration of calcium and phosphate ions into the enamel pores as shown in Figure (1,e) allowed the yellow stains present in coffee to permeate the lesions.

According to the results of the present study, time of immersion had a significant effect on the color stability of WSLs. Color change was the highest at 8 weeks. These results are congruent with Lee J et al. (2015) and Nasim et al. (2010) who stated that as the immersion time increase, specimens tend to be darker and color changes become more intense.17,39 This can be clarified by the prolonged interaction between the chemical products of the staining solution and the WSL, resulting in significant increase of color intensity rather than its saturation.14 For all surface treatments, immersion in coffee has reduced ∆L and increased ∆E values over time. Moreover, the presence of brown pigments in coffee has directed the a* and b* values towards red and yellow changes, respectively.3

Additionally, it should be pointed out that the absence of tooth brushing and dilution of staining solution by saliva may have potentiated the staining susceptibility.3 For that purpose and to assure the measuring of only the incorporated internal stains within the WSL, re-polishing of all groups before each color measurement was mandatory in order to remove the superficial stains from the surface layer.12,40
Therefore, resin infiltration is considered an effective treatment in masking and reducing the staining susceptibility of WSLs after treatment.\textsuperscript{35,36} However, patients should be warned about their potential for staining over time. Furthermore, minimizing the consumption of such chromogenic beverages associated with proper oral hygiene measures should be considered to increase the longevity of these esthetic outcomes.\textsuperscript{3}

**CONCLUSION**

Under the limitations of this study, it could be concluded that: Resin infiltrant (ICON®) can be considered an effective treatment in masking and reducing long-term staining susceptibility of white spot lesions after treatment.

**RECOMMENDATIONS**

CPP-ACP (GC Tooth Mousse®) seems to need a longer time of application, therefore adequacy of masking of white spot lesions must be verified prior to testing color stability.
